Persistent effects of pre-Columbian plant domestication on Amazonian forest composition

The extent to which pre-Columbian societies altered Amazonian landscapes is hotly debated. We performed a basin-wide analysis of pre-Columbian impacts on Amazonian forests by overlaying known archaeological sites in Amazonia with the distributions and abundances of 85 woody species domesticated by pre-Columbian peoples. Domesticated species are five times more likely than nondomesticated species to be hyperdominant. Across the basin, the relative abundance and richness of domesticated species increase in forests on and around archaeological sites. In southwestern and eastern Amazonia, distance to archaeological sites strongly influences the relative abundance and richness of domesticated species. Our analyses indicate that modern tree communities in Amazonia are structured to an important extent by a long history of plant domestication by Amazonian peoples.

Increasing evidence suggests that the modern floristic composition and structure of Amazonian forests have been influenced by past human activity (1). Seasonal forests and river margins are thought to have been modified more intensively than were wetter and less accessible forests (2, 3). At the basin scale, the magnitude to which pre-Columbian peoples transformed forests is still unclear (4, 5). Humans transformed forests in many ways, through plant cultivation (preceded by cutting and burning), seed dispersal and propagation, and in situ tending of useful resources, such as domesticated plants (6, 7).

Domestication of plant populations is a result of the human capacity to overcome selective pressures of the environment by creating land-
soil fertility \(^{(19)}\); and may be the result of dispersal limitation \(^{(20)}\). We evaluated whether the plant domestication process acted together with evolutionary and environmental processes to determine the ecological patterns documented in Amazonian forests.

Using 1170 forest plots of the Amazon Tree Diversity Network (ATDN), ter Steege and co-authors \(^{(17)}\) identified 4962 species, estimated that about 16,000 woody species occur in Amazonia, and showed that only 227 hyperdominant species dominate Amazonian forests. We used 1091 ATDN plots located in nonflooded lowland Amazonian forests to provide a list of domesticated species on the basis of evidence of at least incipient domestication processes in Amazonia and elsewhere in the Americas. We identified 85 woody species with populations incipiently, semi-, or fully domesticated by pre-Columbian peoples (hereafter, domesticated species listed in database S1). We found that 20 of these 85 domesticated species are hyperdominants: five times higher than the number of hyperdominant species expected by chance.

We then tested whether forests closer to archaeological sites and rivers have higher abundance and richness of domesticated species. Forest composition was evaluated in association with numerous types of archaeological sites, including pre-Columbian habitation sites (with and without anthropogenic soils), earthworks (mounds, causeways, raised fields, and terraces), rock art (paintings and petroglyphs), and identified eco-archaeological regions (fig. S2) \(^{(12, 24)}\). We included eco-archaeological regions in the analysis because they indicate environmental settings with large and abundant pre-Columbian earthworks \(^{(22)}\). We also used margins of navigable rivers as proxies for pre-Columbian settlements because they are good predictors of anthropogenic soils in Amazonia \(^{(26)}\). Our analyses also accounted for the effects of different geological regions of Amazonia and for four local environmental conditions: soil cation exchange capacity (CEC), soil pH, rainfall seasonality, and height above the nearest drainage (HAND; a proxy for water-table depth). These variables were selected because they influence forest composition in Amazonia \(^{(19, 21–23)}\) and are available for basin-wide analysis.

We found a significantly higher abundance and richness (in absolute and relative terms) of domesticated species in southwestern Amazonian forests, followed by northwestern, southern, and eastern forests, and the lowest values in the Guiana Shield (Fig. 2 and fig. S3). The total number of individuals of domesticated species per hectare (abundance) ranged from 0 to 292, and the total number of domesticated species (richness) ranged from 0 to 19. The relative abundance of domesticated species has not been recorded. Shading shows the interpolated distribution of each species by use of loess spatial interpolation \(^{(17)}\). The range of relative abundance in plots (RelAb) and the loess spatial interpolation in individual grid cells (fit) are reported in percentage above each map. Maps were created with custom R scripts. Amazonia was divided into six geological regions (NWA, northwestern Amazonia; SWA, southwestern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia). [Base map source (country.shp, rivers.shp): Esri (www.esri.com/data/basemaps, copyright Esri, DeLorme Publishing Company.)

**Fig. 1.** Distribution maps of five domesticated hyperdominant species in Amazonian forests and their probable origins of domestication. (A to E) Distribution maps were estimated for five domesticated species that are hyperdominants: (A) *Bertholletia excelsa*, (B) *Inga ynga*, (C) *Pourouma cecropifolia*, (D) *Pouteria caimito*, and (E) *Theobroma cacao*. The origin of domestication is shown by the symbol ‘+++’ for known origin and by the symbol ‘++’ for hypothetical origin \(^{(13, 42)}\). Sizes of black dots indicate the relative abundance of the domesticated species in plots where the species has been recorded. Red dots indicate plots where each domesticated species has not been recorded. Shading shows the interpolated distribution of each species by use of loess spatial interpolation \(^{(17)}\). The range of relative abundance in plots (RelAb) and the loess spatial interpolation in individual grid cells (fit) are reported in percentage above each map. Maps were created with custom R scripts. Amazonia was divided into six geological regions (NWA, northwestern Amazonia; SWA, southwestern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia). [Base map source (country.shp, rivers.shp): Esri (www.esri.com/data/basemaps, copyright Esri, DeLorme Publishing Company.)
ranged from 0 to 61%, and the relative richness ranged from 0 to 19%. Forests with a diverse assemblage of domesticated species tended to have a high abundance of these species (fig. S4). The abundance of all domesticated species was, however, mostly due to 20 hyperdominant species. Domesticated hyperdominant species were more widespread across Amazonian forests than were nondomesticated hyperdominant species. We found that 70% of the 20 domesticated hyperdominant species studied here occur in all Amazonian regions (database S1) versus only 47% of the 207 nondomesticated hyperdominant species (27). Most of the domesticated species that are hyperdominant have incipiently domesticated populations, rather than fully domesticated ones. This finding suggests that humans were probably managing hyperdominant species in forests instead of investing their efforts to fully domesticate populations. Humans may have fully domesticated populations of plant species that were rare in nature and easily adapted to anthropogenic landscapes.

We found that forests closer to archaeological sites had greater abundance and richness (in relative and absolute terms) of domesticated species at the Amazonia-wide level (Fig. 3 and fig. S5). In four of the six Amazonian regions, the relative and absolute richness of domesticated species decreased with distance from archaeological sites or rivers, and in three of these four regions the relative and absolute abundance of domesticated species also decreased with distance from archaeological sites or rivers. These results reveal that forests closer to archaeological sites or rivers within these regions harbor a richer and larger assemblage of domesticated species than forests elsewhere. The relative abundance of domesticated hyperdominant species also decreased with distance from archaeological sites (Fig. 4). In contrast, we tested whether nondomesticated hyperdominant species in three control groups were negatively affected by the distance from archaeological sites, and we did not find a significant negative relation for any control group (Fig. 4). Additionally, nondomesticated hyperdominant species dispersed primarily by primates were more abundant farther from archaeological sites within forests in southern Amazonia and the Guiana Shield (Fig. 4), potentially as a result of heavy hunting around villages (16). Although the absolute and relative abundance of domesticated species in forest plots decreased with distance from navigable rivers in the Guiana Shield, the opposite was observed for the distance from archaeological sites within this region. One possible explanation is insufficient information about the distribution of archaeological sites along tributary rivers, so moving away from a known archaeological site may increase the proximity to other sites that have not been mapped yet. Archaeological surveys into interfluvies of major rivers in Central Amazonia documented numerous anthropogenic soils along tributary rivers, showing that these areas were also densely occupied (27).

The map showing the density of archaeological sites in 1°-grid cells (areas of ~110 km²) indicated large areas of Amazonia without any archaeological site (fig. S6) and revealed that some plots with high values of the relative abundance of domesticated species are located in these grid cells, most likely reflecting the lack of surveys. Although simple regressions showed a pronounced decrease of human impact in forests up to 25 km from archaeological sites and 10 km from rivers (figs. S7 to S11), the strongest human impact was detected in forests located on archaeological sites or within eco-archaeological regions in southwestern and eastern Amazonia. Dominance of domesticated species may, therefore,

Table 1. Mean, median, minimum, and maximum values of all human and environmental variables used in the multiple regression models. Values were calculated at the Amazonia-wide level (All) and region level (NWA, northwestern Amazonia; SWA, southwestern Amazonia; SA, southern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia).

</table>
help predict the occurrence of archaeological sites in Amazonian forests. Guiana Shield plots, for example, with an average of 30% of individuals of domesticated species located close to river margins, but more than 120 km away from an archaeological site, can be used to test this hypothesis and indicate that a widespread survey of archaeological sites along tributaries in interfluvial areas is critical.

Environmental conditions also controlled the abundance and richness of domesticated species (Fig. 3 and fig. S6) and may have influenced where and how humans shaped forests through time. We found that environmental conditions explained most (up to 30%) of the variation in the relative abundance and richness of domesticated species in Amazonian regions (Fig. 5), whereas the proxies for past human impacts explained up to 20%. Approximately 70% of the variation remains unexplained by either human or environmental factors in most of the regions.

Fig. 2. Spatial variation of 85 domesticated species across Amazonia. (A to D) Maps showing (A) the spatial variation of the total number of individuals of domesticated species (abundance) per hectare (ha), (B) the relative abundance of domesticated species, (C) the total number of domesticated species (richness) per plot, and (D) the relative richness of domesticated species in lowland plots in six geological regions of Amazonia (NWA, northwestern Amazonia; SWA, southwestern Amazonia; SA, southern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia). Black circles show the observed values of absolute abundance (A) and relative abundance (B), ranging from 0 to 292 individuals of domesticated species per 1 ha and 0 to 61% of the total number of individuals, and the observed values of absolute richness (C) and relative richness (D), ranging from 0 to 19 domesticated species per plot and 0 to 19% of the total number of species. The white-green background shows the interpolation of the observed values (in percent) in each plot modeled as a function of latitude and longitude on a 1°-grid cell scale by use of loess spatial interpolation (17). Maps were created with custom R scripts. [Base map source (country.shp, rivers.shp): Esri (www.esri.com/data/basemaps, copyright Esri, DeLorme Publishing Company)].
Fig. 3. The relative abundance and richness of domesticated species as a function of human and environmental variables. (A and B) Standardized regression coefficients for (A) the relative abundance and (B) the relative richness of 85 domesticated species as a function of human factors (distance to archaeological sites and eco-archaeological regions, distance to navigable rivers) and environmental conditions (soil CEC, soil pH, number of dry months, and HAND). Circle size represents the relative contribution of the predictors, shown by standardized coefficients at the Amazonia-wide level (All) and region-level regression models (NWA, northwestern Amazonia; SWA, southwestern Amazonia; SA, southern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia). Red circles indicate negative effects, and blue circles indicate positive effects. Standardized coefficients are presented only for significant relations analyzed in the models (P ≤ 0.05). Adjusted coefficient of determination (R²) and significant codes (***P ≤ 0.001; **P ≤ 0.01; *P ≤ 0.05; ns, P > 0.05) are presented for the effect of regions at the Amazonia-wide level (All) and all regression models.

Fig. 4. The relative abundance of hyperdominant species as a function of human and environmental variables. (A to D) Standardized regression coefficients for (A) the relative abundance of 20 domesticated species that are hyperdominants, (B) the relative abundance of 20 nondomesticated species that are hyperdominants and primarily dispersed by primates, (C) the relative abundance of 20 nondomesticated species that are hyperdominants and not dispersed by primates, and (D) the relative abundance of 20 nondomesticated species selected at random, as a function of human variables (distance to archaeological sites and eco-archaeological regions, and distance to navigable rivers) and environmental variables (soil CEC, soil pH, number of dry months, and HAND). Circle size represents the relative contribution of the predictors, shown by standardized coefficients at the Amazonia-wide level (All) and region-level regression models (NWA, northwestern Amazonia; SWA, southwestern Amazonia; SA, southern Amazonia; CA, central Amazonia; GS, Guiana Shield; and EA, eastern Amazonia). Red circles indicate negative effects, and blue circles indicate positive effects. Standardized coefficients are presented only for significant relations analyzed in the models (P ≤ 0.05). Adjusted R² and significant codes (***P ≤ 0.001; **P ≤ 0.01; *P ≤ 0.05; ns, P > 0.05) are presented for the effect of regions at the Amazonia-wide level (All) and all regression models.
The data available for this broad-scale analysis are based on forest plots and archaeological sites unequally distributed across the study area and on interpolations of environmental conditions. Hence, the data used may not capture the real variation of past human and environmental factors across the basin. Even so, the relative abundance and richness of domesticated species were higher in the southern periphery of the basin (Fig. 2) and increased with rainfall seasonality at the Amazonia-wide level (Fig. 3). Seasonal and open forests in transitional zones were important ecosystems for early humans, who started the domestication of some plants (28), and the longest pre-Columbian occupation sequences have been found either in the southern periphery of the basin or near the estuary of the Amazon River (29). In seasonal forests of southwestern Amazonia, where two major crops most likely originated (manioc, Manihot esculenta, and peach palm, Bactris gasipaes) (33), plant populations that also responded well to selection and propagation were widely dispersed (33). For instance, sweet manioc was domesticated in southwestern Amazonia before the initial development of small-scale farming societies in the mid-Holocene and expanded widely (28, 30). It was also from the southwestern periphery that two major languages expanded and where the oldest anthropogenic soils have been found, dated from around 4800 B.P. (6, 31). The Arawak language family probably originated in southwestern Amazonia and expanded across Amazonia associated with the early development of farming villages (32). The upper Madeira River is the homeland of the Tupi language family, which also spread widely (33). In southwestern Amazonia, the combination of rainfall seasonality (Table 1), forest-savanna transition (34), high cultural diversity (35), and a long history of forest transformation encompassing landscape engineering by pre-Columbian societies (25) resulted in forests containing diverse and abundant assemblages of domesticated species.

Soil and terrain conditions also determined forest composition (36) and influenced the abundance and richness of domesticated species in forest plots (Fig. 3). We found in some regions higher relative abundance and richness of domesticated species on soils with lower pH. Plots with shallow water tables also concentrated domesticated species. This pattern is driven by dense stands of some species (such as Mauritia flexuosa, Euterpe oleracea, E. precatoria, and Oenocarpus bataua) on poorly drained soils of Amazonia (37).

Although potential confounding effects of some correlations between human and environmental factors may exist (for example, human settlements located in seasonal forests on poorly drained soils of southwestern Amazonia), we found that human influence is exclusively responsible for about half of the explained variation of the abundance, relative abundance, richness, and relative richness of domesticated species in the southwestern and eastern regions (Fig. 5 and fig. S12). The association between domesticated species and archaeological sites raises a chicken-and-egg question: Did humans enrich forests in southwestern and eastern Amazonia with domesticated species, or did humans choose to live close to forests naturally rich in these species? Our approach cannot demonstrate causality, but the first alternative is most probable, given the sum of other evidence that also supports the influence of past societies in increasing domesticated species abundance and richness in forests. First, numerous archaeological sites were found in all geological regions (fig. S2), which shows that pre-Columbian human societies were distributed across all of Amazonia (1) and created new landscapes for domesticated plants under different environmental conditions (Table 1). Dramatic changes in phytolith assemblages have been found in ancient anthropogenic soils before, during, and after human occupation, indicating that humans transform forest composition once they occupy an area (38). Second, assemblages of up to 19 domesticated species with different geographical distributions and distinct ecological preferences tend to occur in forests close to archaeological sites (Fig. 3 and fig. S5). As an example, we found a set of domesticated species at one forest plot (Attalea maripa, Astrocarum murumuru, Bertholletia excelsa, Garcinia macrophylla, Hevea brasiliensis, Oenocarpus bataua, and Theobroma spp.) that would be unlikely to occur by chance at the same location because of their distinct ecological niches. Third, species domesticated in one particular environmental setting had wide geographical distributions and tended to be more abundant in locations not associated with their known or hypothetical origins of domestication (Fig. 1 and fig. S1) (35). For instance, cocoa (Theobroma cacao) was first domesticated in wet forests on nutrient-rich soils of northwestern Amazonia and is currently more abundant in southwestern and southern forests (39).

Although it is possible that the origin of domestication of some species is not well identified, this is unlikely for species for which extensive morphological and genetic studies have been done (more details in supplementary text, sections 1 to 11). Domesticated species for which information about their origins of domestication exists originated in the periphery of Amazonia (13). Species can have wild populations in one part of Amazonia (where the domestication process started) and incipiently, semi-, or fully domesticated populations in other parts of the basin. Fully domesticated populations show substantial morphological and genetic changes and depend on human management for their long-term survival, whereas incipiently domesticated plants can survive and reproduce without humans, as is the case of most hyperdominant domesticated species. Many domesticated species were dispersed from their origin of domestication to other locations where large pre-Columbian populations lived, and these species eventually accumulated greater intraspecific diversity (13). Our results suggest that plant species that responded well to selection and propagation were widely cultivated and dispersed within and outside their natural range (6, 7) by different societies and at different moments in time. The influence of modern indigenous and nonindigenous societies in the past 300 years on the distribution of some domesticated species may be stronger than the effect of earlier societies. For instance, in the late 17th century, Portugal and Spain stimulated plantations of cocoa trees in Amazonia (40), which—associated with pre-Columbian cultivation—may have increased the abundance of cocoa trees in southwestern Amazonian forests even more.

Our results suggest that past human interventions had an important and lasting role in the distribution of domesticated species found in...
modern forests, despite the fact that the location of many archaeological sites is unknown. Almost four-tenth of all domesticated species are hyper-dominant, and besides their socioeconomic importance, they can also help unravel the human history of Amazonian forests, which is largely overlooked by ecological studies. Detecting the widespread effect of ancient societies in modern forests not only strengthens efforts to conserve domesticated and useful wild-plants populations, which is of critical importance for modern food security (47), but also strongly refutes ideas of Amazonian forests being untouched by man. Domestication shapes Amazonian forests.

Persistent effects of pre-Columbian plant domestication on Amazonian forest composition
Science 355 (6328), 925-931. [doi: 10.1126/science.aal0157]
Past human influences on Amazonian forest

The marks of prehistoric human societies on tropical forests can still be detected today. Levis et al. performed a basin-wide comparison of plant distributions, archaeological sites, and environmental data. Plants domesticated by pre-Columbian peoples are much more likely to be dominant in Amazonian forests than other species. Furthermore, forests close to archaeological sites often have a higher abundance and richness of domesticated species. Thus, modern-day Amazonian tree communities across the basin remain largely structured by historical human use.
